Appendix: Projections of new cases and \% increase in numbers by year, sex and cancer site ..... 78

## Introduction

Projections of the number of cancer cases are valuable in setting priorities for prevention and in anticipating the demand for cancer services. Adequate health service planning, especially with regard to staff training and recruitment, and the development of long-term capital projects such as radiotherapy units, requires estimates of the likely future burden of cancer.

This is the third set of projections of future cancer cases produced by the National Cancer Registry. Although a wide range of methods is available for projecting cancer incidence and mortality [1-8] we have, to a large extent, adhered to the methods used in previous reports [ $5,9,10$ ], as they have been proven over time and also provide some continuity.

This report presents

1. Current trends in numbers of new cancers and incidence rates over the period 1994 to 2010.
2. Estimates of the future number of cancer cases, at five year intervals from 2015 to 2040.

These estimates are presented for all cancer types combined, both with, and without, the inclusion of non-melanoma skin cancers; and for 22 individual cancers or cancer groups. At least two sets of estimates are given for each cancer, based on different methodologies for projecting future trends in incidence. The expected number of treatments (for surgery, chemotherapy and radiotherapy separately) for each cancer type, based on 2010 treatment utilization patterns, is also provided for 2025.

## 1. Summary

Cancer incidence data from the National Cancer Registry from 1994 to 2010 and population projections from the Central Statistics Office have been combined to estimate the number of new cancer cases expected in the years $2015,2020,2025,2030,2035$ and 2040, as well as the number of first treatment episodes expected in 2025. A number of different estimation methods were used.

The total number of new invasive cancer cases (including non-melanoma skin cancer) is projected to increase by $84 \%$ for females and $107 \%$ for males between 2010 and 2040, based only on changes in population size and age distribution (demography). If trends in incidence since 1994 are also taken into account, the number of cases is expected to increase by between $86 \%$ and $125 \%$ for females (depending on the method of projection used) and by between $126 \%$ and $133 \%$ for males. The projected increases are a little less than those published by the Registry previously, mainly due to changes in the CSO population projections following the 2011 census. If non-melanoma skin cancer is excluded, the numbers are expected to increase by $81 \%$ for females and $108 \%$ for males, based on demography alone. If trends in incidence are taken into account the expected increase in incidence for females is $48-112 \%$ and for males $114 \%-128 \%$.

With the exception of leukaemia in males, the number of cancers is projected to increase for all sites between 2010 and 2040 (Figure 1.1). The most rapidly increasing cancers in coming decades are expected to be those of skin—both melanoma and non-melanoma-in both sexes. Cancers of the upper gastrointestinal tractoesophagus, pancreas and hepatobiliary tract-are also expected to increase by over $100 \%$ by 2040.

Of the other common cancers

- cancers of the colon and rectum are projected to increase largely in line with demographic change, by 120\%-130\% between 2010 and 2040;
- lung cancer incidence is rising more rapidly in females than in males and by 2040 the rate is projected to increase by $136 \%$ in females (Nordpred) and $52 \%$ in males;
- female breast cancer is difficult to project, due to recent short-term variations in incidence trends, but is expected to increase by about $130 \%$ between 2010 and 2040 . However one HD model projects a much slower rate of increase for females;
- future trends in prostate cancer rates are unclear; the HD models project an increase of $104 \%$ in new cases by 2040, while Nordpred projects an increase of 288\%; the latter, which is based on the rapid increase in rate in the early 2000s, driven by PSA testing, seems implausible;
- the models for cancer of the bladder and for leukaemia in males were heterogeneous, and future trends in these are difficult to project.

Although demographic change will be the main factor driving an increase in cancer numbers, trends in risk factor prevalence will also have an impact. $40 \%$ of the total cancer risk in the UK population ( $44 \%$ in males, $35 \%$ in females) has been attributed to five lifestyle factors-tobacco, diet, overweight/obesity, alcohol and low physical activity [11]. The attributable risks in Ireland are likely to be similar. Smoking prevalence in Ireland is high, although decreasing slowly, and more rapidly in males than females [12]. Obesity and overweight are increasing in both sexes, as is alcohol consumption (although there may have been a recent decrease in the latter) [13, 14]. Levels of self-reported physical activity are low, and have not changed appreciably in the last two decades [15]. Apart from changes in risk factor prevalence, the expansion of population-based screening for breast, cervical and colorectal cancers may also bring some transient increases in cancer incidence. Modelling the expected impact of all of these changes is beyond the scope of this report, but would be worthwhile.

Figure 1.1. Projected percentage increase in number of cancer cases 2010-2040, by cancer site and sex females males

The models project an increase of about $50 \%$ in cancer cases by 2025, and treatment numbers are expected to increase correspondingly. The total number of patients having cancer-directed surgery is projected to increase by $50 \%-55 \%$ between 2010 and 2025, the number having chemotherapy by $42 \%-48 \%$ and the number having radiotherapy by $32 \%-35 \%$. These changes, combined with increasing survival, will inevitably increase the burden on the cancer services. With the ageing of the population, and improving life expectancy, the median age of cancer patients at diagnosis will increase. Cancers will be diagnosed in an older population, which will have different needs, and clear guidelines will be needed on the assessment and treatment of older patients. The growing availability and use of ever more sophisticated and expensive targeted therapy will contribute to better survival, but the high costs of these therapies, especially for advanced disease, will need to be balanced against other priorities in cancer care.

The coming decades will challenge the Irish cancer services to reduce the burden of cancer and to improve the quality of care, in the face of changing lifestyles and an increasing and more complex cancer burden. These projections, in indicating the likely future burden of cancer in the absence of effective primary prevention, can quantify the benefits and cost savings from effective action to reduce cancer risk. They can also inform decisions on allocation of resources between prevention, early detection and treatment.

## 2. Methods

Three methods have been used in this report to project cancer numbers:

1. demographic projections, which apply the average age-specific incidence rates for 2006-2010 to the future projected populations. These assume that there are no changes in the underlying incidence rates over time and therefore make the fewest assumptions;
2. age-period methods, as described by Hakulinen and Dyba [5, 9, 10], which apply linear, non-linear and log-linear models to historical data;
3. the Nordpred method, which uses a special version of the age-period-cohort model $[8,16]$ with a power link.

Details of the application of these methodologies are given below.
The advantages and limitations of cancer projections have been described in previous reports [17-19]. It is important to note that this report gives projections of current data into the future, and not predictions. To make predictions, we would require knowledge of trends in underlying risk, which are not available in most cases.

## $2.1 \quad$ Cancer sites

Data were modelled for 24 invasive cancer sites or groups of sites, including all invasive cancers combined, with and without the inclusion of non-melanoma skin cancer (Table 2.1).

Table 2.1. Cancer sites and groups of sites for which projections are presented in this report

| 1. Cancer site | ICD10 codes |
| :--- | :--- |
| 1. All invasive cancers | C00-C96 |
| 2. | C00-C43; C45-C96 |
| 3. Head and neck | C01-C14, C30, C31, C32 |
| 4. Oesophagus | C 15 |
| 5. Stomach | C 16 |
| 6. Colon | C 18 |
| 7. Rectum and anus | $\mathrm{C} 19-\mathrm{C} 21$ |
| 8. Liver, gallbladder and biliary tract | $\mathrm{C} 22-\mathrm{C} 24$ |
| 9. Pancreas | C 25 |
| 10. Lung | C 34 |
| 11. Melanoma of skin | C 43 |
| 13. Non-melanoma cancer of skin | C 44 |
| 14. Female breast | C 50 |
| 15. Cervix uteri | C 53 |
| 16. Corpus uteri | C 54 |
| 17. Ovary | C 56 |
| 18. Prostate | C 61 |
| 19. Kidney and renal pelvis | $\mathrm{C} 64-\mathrm{C} 65$ |
| 20. Bladder | C 67 |
| 21. Brain and other central nervous system | $\mathrm{C} 70-\mathrm{C} 72$ |
| 22. Hodgkin's lymphoma | C 81 |
| 23. Non-Hodgkin's lymphoma | $\mathrm{C} 22-85$ |
| 24. Leukaemia | $\mathrm{C} 91-\mathrm{C} 95$ |

### 2.2 Projected populations

The cancer case projections are based on the population projections of the Irish Central Statistics Office (CSO) [20]. A number of future projections have been published simultaneously by the CSO, based on different assumptions regarding mortality, migration (M) and fertility (F). These give expected population numbers for each year 2015-2046, by five year age group and sex.

Mortality rates are assumed to decrease, which will result in gains in life expectancy at birth from:

- 77.9 years in 2010 to 85.1 years in 2046 for males
- 82.7 years in 2010 to 88.5 years in 2046 for females.

Two fertility assumptions were used:

- F1: Total Fertility Rate to remain at the 2010 level of 2.1 for the lifetime of the projections
- F2: Total Fertility Rate to decrease to 1.8 by 2026 and to remain constant.

Four migration assumptions were used:

- MO: No net migration
- M1: Net migration returning to positive by 2016 and rising steadily thereafter to $+30,000$ per annum by 2021
- -19,100 annual average per annum in 2011/2016 .
- $+18,200$ annual average per annum in 2016/2021
- $+30,000$ per annum in 2021/2026
- $+30,000$ per annum in 2026/2046.
- M2: Net migration returning to positive by 2018 and rising thereafter to $+10,000$ per annum by 2021
- -21,600 annual average per annum in 2011/2016
- $+4,700$ annual average per annum in 2016/2021
- $+10,000$ per annum in 2021/2026
- $\quad+10,000$ per annum in 2026/2046.
- M3: Net migration remaining negative for the whole period
- $-25,100$ annual average per annum in 2011/2016
- -10,000 annual average per annum in 2016/2021
- $-5,000$ per annum in 2021/2026.

Eight different population projections, based on combinations of the above assumptions, have been published by the CSO: MOF1, M0F2, M1F1, M1F2, M2F1, M2F2, M3F1 and M3F2. The mortality assumptions are the same for all projections. The fertility assumptions, which will affect only the population aged under 30 years by 2040, will have a minimal impact on numbers of cancer cases over the period studied, since cancer is predominantly a disease of the elderly. Projected 2015 to 2040 populations for the M0F1 assumptions are shown in Table 2.2. These project a $15 \%$ increase in the male population and a $14 \%$ increase in the female population between 2015 and 2040. The size of population change ranges from a fall of 20-22\% in those aged $35-49$ to an increase of $170 \%$ in males and $298 \%$ in females aged over 85 .The population aged over 70 is projected to increase by $136 \%$ (females) and $119 \%$ (males).

Figure 2.1 shows the differences between the projected 2015 and 2040 populations for the different assumptions. The largest 2015-2040 differences for all the assumptions are in the youngest age groups, which have the lowest cancer rates. For most ages over 50 the projections suggest a population increase of just over 50,000 in each five-year age group.

Table 2.2. Projected MOF1 populations 2015-2040

|  | year |  |  |  |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |

Figure 2.1. Projected population increase 2015-2040, by age group and population growth model

Figure 2.2 shows the impact of the different population assumptions on projected overall cancer numbers, assuming that incidence rates remain constant over the period (i.e. method 3, demographic projections, as described on page 2). As most of the difference between the models is in the population under 60, who have a low cancer incidence, the impact of using different population projections is small, $6-7 \%$ of the overall
expected numbers in 2040. The overall number of invasive cancer cases, based only on population change, is projected to increase from 28,400 in 2010 to between 54,700 and 58,200 in 2040. The M1 assumptions give the highest projected population in 2040, and consequently the largest number of new cancer cases, while the M3 assumptions give the lowest. Throughout the rest of this report we have used the MOF1 populations for making projections as these make the fewest assumptions and produce projected case numbers which are approximately midway between the lowest and highest estimates.

Figure 2.2. Case projections based on projected populations, all invasive cancers

### 2.3 Historic incidence rates

Projections are based on the assumption that current trends in incidence will continue into the future. The precision of the model is greatest if a long prior period of observation can be used. Where possible, all years of data from the National Cancer Registry, beginning from 1994, were used. For the Hakulinen and Dyba (HD) models (method 1 on page 2), trends in age-standardised incidence rate for each cancer were tested for linearity over the period 1994-2010, using Joinpoint software [21]. Joinpoint was constrained so that changes in rate over periods less than five years were not modelled. For cancers with a linear trend in incidence rate over the full period 1994-2010, cancer rates over this period have been used to construct the model. For other cancers, the most recent linear trend in the historic incidence rate data (the base of projection) for each cancer site was fitted using four different HD models (see section 2.4), for each sex separately, where relevant. For Nordpred (method 2 on page 2), aggregated incidence data for three five-year periods were used: 19962000, 2001-2005 and 2006-2010. This is the minimum number of periods which is possible with the Nordpred software. Demographic projections were based on the average age-specific incidence rates in the period 20062010 inclusive. Details of the models fitted to the data, and the historic period used, are given in the corresponding chapter for each cancer site or combination of sites.

Only invasive cancers are considered in this report, as trends in non-invasive cancers (predominantly in situ cancers) are largely dependent on screening activity rather than underlying risk, and so cannot be convincingly modelled.

## $2.4 \quad$ Model fitting

## 1. Demographic projections

Demographic projections were produced by applying the population projections to the average age-specific incidence rates for each age group (0-34, 35-39, 40-44, 45-49, 50-54, 55-59, 60-64, 65-69, 70-74, 75-79 and 80+) for each cancer for the years 2006-2010.

## 2. Hakulinen/Dyba age-period methods

Hakulinen and Dyba [5, 9, 10] propose four age-period models to fit and project incidence data. These are:
Model 1. $\quad n_{i, t}=p_{i, t} \times\left(\alpha_{i}+\beta_{i} t\right) \quad$ where
Model 2. $\quad n_{i, t}=p_{i, t} \times e^{\left(\alpha_{i}+\beta_{i} t\right)} \quad n=$ number of cases
Model 3. $\quad n_{i, t}=p_{i, t} \times e^{\left(\alpha_{i}+\beta t\right)} \quad p=$ population at risk
Model 4. $\quad n_{i, t}=p_{i, t} \times\left(\alpha_{i} \times(1+\beta t) \quad i=\right.$ age group
$t=$ time period
$\alpha$ is the intercept
$\beta$ the slope
These models use single year of incidence data and calculate projected numbers of cases, age-standardised incidence rates and $95 \%$ confidence limits for both.

Hakulinen/Dyba (HD) model 1 is a linear model, which assumes that the cancer incidence rate increases by a fixed amount ( $\beta$ ) annually. It estimates a different slope ( $\beta$ ) for each age-group $i$, which can give a better fit to the data when there are opposing trends for different age groups e.g. an increasing trend for older, but a falling trend for the younger, patients.

Models 2 and 3 are log-linear models, which assume that the incidence rate increases by a fixed proportion ( $\beta$ ) annually. Model 2 allows for a different slope ( $\beta$ ) for each age-group $i$, whereas model 3 does not. These models provide larger estimates of future increase and smaller estimates of decrease than the linear model.

Model 4 is a non-linear model, which gives estimates which are similar to those from Model 1. However, the estimates of increase or decrease are always less than for Model 1, and the difference between these models becomes more pronounced with increasing time and/or when the rate of increase is greatest. This model is the most conservative of the four and gives estimates which are closest to the assumption of no change in underlying trend (i.e. demographic change only).

The model with the best fit, as judged by the scaled standard errors of the projections, was used for the projections for each site, with a few exceptions, which are described in the chapters for individual cancers.

## 3. Nordpred

The Nordpred software provides projections for a maximum of four future five-year periods, and does not give confidence intervals for the projections (although these may be calculated using computationally intensive bootstrap methods [22]). It fits a power age-period-cohort model, with a power coefficient of 0.2 , to the historic trends, using a different slope parameter for each age group (0-34, 35-39, 40-44, 45-49, 50-54, 55-59, 60-64, 65-69, 70-74, 75-79 and 80+). This model is intermediate in its assumptions between the HD linear and log models. The Nordpred software gives aggregate case numbers for the four five-year periods 2015-2019, 2020-2024, 2025-2029 and 2030-2034. Projected numbers for the years 2015, 2020, 2025, 2030, 2035 and 2040 were derived from these estimates by linear interpolation and extrapolation.

The application of the four HD models, Nordpred and the demographic projections to the incidence rate of all cancers combined (ICD 10 C00-C96) from 2015 to 2040 is shown in Figure 2.3. For all cancers combined, the projections made by the four models are similar.

As there is an upward trend in age-standardised incidence rate in the historic data for all cancer sites combined, the demographic model gives the lowest projected numbers (Figures 2.3, 2.4). Nordpred projections are within the HD projection limits for females, but are a little below the lower bounds of projection for males, probably because the five-year aggregated data is less affected by small changes in trend around the year 2000. The 95\% confidence limits for the HD four models overlap for most time periods, and these limits are similar for all models. It is important to note that the Nordpred software models each age
group separately and that there can be an apparent discrepancy between the aggregate historic trend and a projection which is based on the sum of trends for different age groups. This also occurs in the HD models (1 and 3) where each age group is fitted to a different slope, and can give an apparent discontinuity between the historic and modelled numbers.

Figure 2.3. Projections of cancer cases based on HD models 1-4, Nordpred and demographic trends, using M0F1 population projections: all invasive cancers

Figure 2.4. Projections of cancer cases based on HD models 1-4 (with 95\% projection limits), Nordpred and demographic trends, using MOF1 population projections: all invasive cancers

Note. Nordpred produces projections for aggregate five-year periods. Figures 2.3 and 2.4 use linear interpolation and extrapolation to project the average midpoint values (2017, 2022, 2027, 2032 and 2037) to the years 2015, 2020, 2050, 2030, 2035 and 2040.

### 2.5 Treatments

For each registered cancer case, the Registry records whether the patient had a specified modality of treatment (cancer-directed surgery, chemotherapy or radiotherapy) as part of the initial treatment regime. The proportion of patients estimated to have each treatment has been extrapolated to 2025, using the projected number of cases and the treatment proportions in 2010. Long-term treatment patterns are difficult to project, so we have given data for a more recent period than for the incidence numbers, and with the caution that the projections depend on an assumption of stability in treatment practices (i.e. no increase or decrease in the use of therapies).

| 1994-2005 $\quad 1.2$ (0.8, 1.7) | 1994-1998 -0.2 (-1.4, 1.0) |
| 2005-2010 3.5 (2.1, 4.9) | 1998-2010 $\quad 1.8$ (1.6, 2.0) |

Case numbers increased between 1994 and 2010. Between 1994 and 1999, there was a significant increase of $1.4 \%$ annually for females and $1.0 \%$ for males, with a sharper increase, $3.5 \%$ annually for females and $4.2 \%$ for males, from 1999 onwards.

The age-standardised incidence rates also increased during 1994-2010, but the increase was not significant for males before 1998. In contrast to case numbers, the overall increase in incidence rate was greater for females.

## Projections

For females, the base of projection for the HD models was 2005-2010, and for males 1998-2010. HD model 4 gave the best fit for both males and females. For both sexes the HD projections of the number of cases were above those due to demographic change alone (Figure 3.3, Table 3.1). Nordpred gave a higher estimate of female incidence and a slightly lower estimate of male incidence than the HD model; these were outside the $95 \%$ confidence limits of the HD model. The models project that female case numbers will increase by $86 \%-125 \%$ between 2010 and 2040 and male cases by $126 \%-133 \%$, with proportionate increases in treatment rates (Table 3.2).

## 4. All invasive cancer sites combined, excluding non-melanoma skin cancer

Non-melanoma skin cancers have been excluded from this analysis, as their recorded incidence is more dependent on casefinding than most other cancers.

## Trends

Figure 4.2. All invasive cancer sites combined, excluding non-melanoma skin; age-standardised incidence rates 1994-2010

Case numbers increased between 1994 and 2010 (Figure 4.1). This trend was not significant between 1994 and 2000, but from 2000 onwards the numbers increased by $4.5 \%$ annually for females and $6.0 \%$ for males. The age-standardised incidence rates also increased during 1994-2010, but the increase was significant throughout-1.5\% annually from 1994 to 2006 and 4.0\% thereafter for females, and $1.6 \%$ annually from 1994 to 2010 for males (Figure 4.2).

## Projections

For females, the base of projection for the HD models was 2006-2010, and for males 1994-2010. HD model 2 gave the best fit for females and model 4 for males. For females the HD projections of the number of cases were below those due to demographic change alone while for males they were very close (Figure 4.3, Table 4.1). Nordpred gave a higher estimate of female incidence and a slightly lower estimate of male incidence than the HD model; these were outside the $95 \%$ confidence limits of the HD model. The models project that female case numbers will increase by $48 \%-112 \%$ between 2010 and 2040; male cases are projected to increase by $114 \%-128 \%$ in the same period, with proportionate increases in treatment rates (Table 4.2).

## Trends

Figure 5.1. Cancer of the head and neck; case numbers, 1994-2010

Figure 5.2. Cancer of the head and neck; age-standardised incidence rates 1994-2010
females
males

Estimated annual percentage change ( $95 \%$ confidence limits) 1994-2010

Estimated annual percentage change ( $95 \%$ confidence limits)
1994-2010 $0.3 \quad(-0.6,1.3)$
Case numbers increased for females by $1.6 \%$ annually between 1994 and 2001 and by $7.9 \%$ annually from 2001 onward. For males there was no significant trend in numbers until 2001 and a $5.2 \%$ increase thereafter (Figure 5.1). Age-standardised incidence rates for females increased by $3.7 \%$ annually between 1994 and 2010, but there was no significant change for males (Figure 5.2).

## Projections

For both sexes the base of projection for the HD model was 1994-2010. HD model 4 gave the best fit for females, and model 3 for males. For both sexes the HD estimates were close to those due to demographic change alone (Figure 5.3, Table 5.1). The Nordpred estimates were much higher than the HD estimates for females, and a little higher for males; the latter was mostly within the HD model $95 \%$ confidence limits. The models project that female case numbers will increase by $46 \%-128 \%$ between 2010 and 2040 and male cases by $66 \%-108 \%$, with proportionate increases in treatment rates (Table 5.2).

## 6. Cancer of the oesophagus

Cancer of the oesophagus is of two main types: squamous carcinoma and adenocarcinoma. Squamous carcinomas have remained fairly constant in number since 1994, but adenocarcinomas are increasing rapidly, by $4 \%$ a year for females and $5 \%$ for males [23]. Due to the small number of cases, it was not feasible to model these histological types separately, and projections are presented here for all oesophageal cancers combined.

## Trends

Figure 6.3. Cancer of the oesophagus; age-standardised incidence rates 1994-2010

Case numbers did not increase significantly for females from 1994 to 2010, but increased by $2.6 \%$ annually for males (Figure 6.2). Age-standardised incidence fell significantly for females, by 1.0\% a year, and remained constant for males (Figure 6.3).

## Projections

The base of projection for the HD models for both sexes was 1994-2010. HD model 3 gave the best fit for females and model 4 for males. For females the HD estimates were below those due to demographic change alone (Figure 6.4, Table 6.1). Nordpred estimates were close to those of the HD model, but suggest a greater increase in female cases in later years. The models project that female case numbers will increase by $84 \%-123 \%$ between 2010 and 2040 and male cases by $112 \%-160 \%$, with proportionate increases in treatment rates (Table 6.2).

## 7. Cancer of the stomach

## Trends

Figure 7.1. Cancer of the stomach; case numbers, 1994-2010

Figure 7.2. Cancer of the stomach; age-standardised incidence rates 1994-2010

| females | males |
| :---: | :---: |
|  |  |
| Estimated annual percentage change (95\% confidence limits) | Estimated annual percentage change (95\% confidence limits) |
| 1994-2010 $\quad-1.6 \quad(-2.3,-1.0)$ | $1994-2003$ -3.2 $(-4.0,-2.3)$ <br> $2003-2010$ 0.8 $(-0.5,2.2)$ |

Case numbers did not change significantly for females from 1994 to 2010. They fell by $1.5 \%$ annually between 1994 and 2003 but increased for males by $3.5 \%$ annually from 2003 onward (Figure 7.1). Age-standardised incidence rates fell by $1.6 \%$ a year for females. For males there was a significant decrease of $3.2 \%$ annually from 1994 to 2003, with no significant trend after that time (Figure 7.2).

## Projections

The base of projection for the HD model for females was 1994-2010 and for males 2003-2010. HD model 3 gave the best fit for both males and females. For both sexes the HD projections of the number of cases were well below those due to demographic change alone (Figure 7.3, Table 7.1). The Nordpred projections were similar to those of the HD model. The models project that female case numbers will increase by $32 \%-74 \%$ between 2010 and 2040, and male cases by $27 \%-59 \%$, with proportionate increases in treatment rates (Table 7.2).

Figure 8.2. Cancer of the colon; age-standardised incidence rates 1994-2010

Case numbers did not change significantly for females from 1994 to 1998. Between 1998 and 2010 they increased significantly, by $2.4 \%$ annually. For males there was no significant trend from 1994 to 2002 and a significant increase, $4.4 \%$ annually, thereafter (Figure 8.1). Age-standardised incidence rates did not change significantly for females, and rose slightly, by $0.6 \%$ a year, for males during 1994-2010 (Figure 8.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for both males and females. For females the HD estimates were the same as for the Nordpred and demographic models (Figure 8.3, Table 8.1) while for males the demographic projections were intermediate between those from Nordpred and the HD model. The models project that female case numbers will increase by $116 \%-117 \%$ between 2010 and 2040, and male cases by 104\%-156\%, with proportionate increases in treatment rates (Table 8.2).

## 9. Cancer of the rectum and anus

## Trends

Cancers of the rectum and anus consist of three subsites: rectosigmoid junction, rectum and anus. Rectal cancers make up the majority and anal cancers are uncommon (Table 9.1).

Table 9.1. Subsites of cancers of the rectum and anus; number of cases and \% of all cancers of the rectum and anus 2006-2010

|  | females |  |  | males |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| site | ICD10 code | average number of cases | \% of cases | average number of cases | \% of cases |
| rectosigmoid junction | C19 | 55 | 23\% | 86 | 20\% |
| rectum | C20 | 168 | 69\% | 325 | 77\% |
| anus | C21 | 19 | 8\% | 13 | 3\% |

Figure 9.1. Cancer of the rectum and anus; case numbers, 1994-2010
females males

Estimated annual percentage change (95\% confidence limits) 1994-2010 $2.2(1.5,2.9) \quad 1994-2010 \quad 2.2 \quad(1.7,2.7)$

Figure 9.2. Cancer of the rectum and anus; age-standardised incidence rates 1994-2010
females

Estimated annual percentage change ( $95 \%$ confidence limits) 1994-2010 $0.4 \quad(-0.4,1.2)$
males

Estimated annual percentage change (95\% confidence limits) 1994-2010 $0.0 \quad(-0.6,0.6)$

Case numbers increased significantly for females and males from 1994 to 1998 , by $2.2 \%$ a year (Figure 9.1 ). There was no significant trend for either sex in age-standardised incidence rates (Figure 9.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 3 gave the best fit for both males and females. For both sexes the HD projections of the number of cases were almost identical to those due to demographic change alone (Figure 9.3, Table 9.2). The Nordpred projections were within the $95 \%$ confidence limits of the HD model for females, but below them for males. The model projects that female case numbers will increase by $83 \%-110 \%$ between 2010 and 2040 and male cases by $77 \%-105 \%$, with proportionate increases in treatment rates (Table 9.2).

## 10. Cancer of the liver, biliary tract and gallbladder

## Trends

Cancer of the liver, biliary tract and gallbladder (hepatobiliary) cancers consist of hepatocellular carcinoma of the liver, intrahepatic bile duct carcinoma, extrahepatic bile duct carcinoma and a small number of other histological types. $37 \%$ were not histologically verified (Table 10.1).

Table 10.1. Subsites of cancers of liver, biliary tract and gallbladder; number of cases and \% of all cancers of the liver, biliary tract and gallbladder 2006-2010

|  |  | adenocarcinoma |  | hepatocellular carcinoma | other and unspecified types |
| :---: | :---: | :---: | :---: | :---: | :---: |

Estimated annual percentage change ( $95 \%$ confidence limits) 1994-2010
 Estimated annual percentage change ( $95 \%$ confidence limits) 1994-2010 $6.7 \quad(5.2,8.2)$

Case numbers increased significantly for females and males from 1994 to 2010, by 4.2\% annually for females and 6.0\% for males (Figure 10.1). There was also a significant increase in age-standardised incidence rates, $6.1 \%$ annually for females and $6.7 \%$ for males (Figure 10.2). Most of this increase was in adenocarcinoma [24].

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for both sexes (Figure 10.3). The three sets of projections were close for females, but Nordpred projected a higher incidence for males from 2020
onwards than the other methods. The models project that female case numbers will increase by $127 \%-148 \%$ between 2010 and 2040 and male cases by 113\%-155\% (Table 10.2), with proportionate increases in treatment rates (Table 10.3).

## 11. Cancer of the pancreas

## Trends

Figure 11.1. Cancer of the pancreas; case numbers, 1994-2010

Figure 11.2. Cancer of the pancreas; age-standardised incidence rates 1994-2010

Case numbers of cancer of the pancreas increased significantly for females and males from 1994 to 2010, by 2.3\% annually for females and 3.0\% for males (Figure 11.1). There was a slight upward trend in age-standardised incidence rates for both sexes but this was not statistically significant (Figure 11.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for both males and females. The HD projections of the number of cases were close to those due to demographic change alone (Figure 11.3, Table 11.1). The Nordpred and demographic projections for both sexes were mostly within the $95 \%$ confidence limits for the HD models. The models project that female case numbers will increase by 140\%-172\% between 2010 and 2040 and male cases by 129\%-152\%, with proportionate increases in treatment rates (Table 11.2).

## 12. Cancer of the lung

## Trends

Figure 12.1. Cancer of the lung; case numbers, 1994-2010

| females | males |
| :---: | :---: |
|  |  |
| Estimated annual percentage change (95\% confidence limits) Estimated annual percentage change (95\% confidence limits) |  |
| 1994-2010 $\quad 3.9 \quad(3.6,4.2)$ | $1994-2005$ 0.7 $(0.1,1.4)$ <br> $2005-2010$ 3.3 $(1.3,5.3)$ |

Figure 12.2. Cancer of the lung; age-standardised incidence rates 1994-2010
females males

Estimated annual percentage change (95\% confidence limits) 1994-2010 $2.3(2.0,2.7) \quad 1994-2010 \quad-0.7 \quad(-1.0,-0.3)$

Lung cancer case numbers increased significantly for females from 1994 to 2010, by $3.9 \%$ annually. For males the numbers increased by $0.7 \%$ annually from 1994 to 2005 and by $3.3 \%$ thereafter (Figure 12.1). The incidence rates increased by $2.3 \%$ annually in females and decreased by $0.7 \%$ annually in males (Figure 12.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. Two HD models-1 and 4-gave an equally good fit for females, while HD model 4 gave the best fit for males. As the projected number of cases from the two HD models for females is quite different, they are both shown below (Figure 12.3). The Nordpred projections lie between the two HD projections. For males the HD projections were a little above those produced by Nordpred and both were below the demographic projections (Figure 12.3, Table 12.1). The models project that female case numbers will increase by 77\%-196\% between 2010 and 2040 and male cases by $52 \%-72 \%$, with proportionate increases in treatment rates (Table 12.2).

2002-2006 $\quad 1.9 \quad(-4.4,8.8)$
2006-2010 $9.2 \quad(5.2,13.3)$

Figure 13.2. Melanoma of the skin; age-standardised incidence rates 1994-2010

The rate of increase in female melanoma numbers varied over the period 1994 to 2010, with a rapid increase ( $9.2 \%$ annually) between 2006 and 2010. For males there was a similar but more constant trend, $7.4 \%$ annually between 1994 and 2010 (Figure 13.1). For both males and females there was also an upward trend in age-standardised incidence rates, $2.8 \%$ annually for females and $5.1 \%$ for males (Figure 13.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 1 gave the best fit for females and males. For both females and males the projected number of cases from the HD models was well above that projected by demographic change or the Nordpred model (Figure 13.3, Table 13.1). The models project that female case numbers will increase by a factor of $93 \%-175 \%$ between 2010 and 2040 and male cases by $134 \%-327 \%$, with proportionate increases in treatment rates (Table 13.2).

## 14. Non-melanoma cancer of skin

## Trends

Figure 14.1. Non-melanoma skin cancer; case numbers, 1994-2010

| females | males |
| :---: | :---: |
|  |  |
| $\begin{array}{ccc}\text { Estimated annual percentage change (95\% confidence limits) } \\ 1994-2000 & 0.4 & (-1.5,2.3) \\ 2000-2010 & 4.5 & (3.7,5.3)\end{array}$ | $\begin{array}{ccc}\text { Estimated annual percentage change (95\% confidence limits) } \\ 1994-2001 & -0.4 & (-1.4,0.6) \\ 2001-2010 & 6.0 & (5.4,6.7)\end{array}$ |

Figure 14.2. Non-melanoma skin cancer; age-standardised incidence rates 1994-2010

There was no significant trend in case numbers for females between 1994 and 2000, followed by a $4.5 \%$ annual increase from 2000 to 2010. For males there was a similar trend, with the increase in case numbers ( $6.0 \%$ annually) beginning in 2001 (Figure 14.1). Trends in age-standardised incidence rates followed the same patterns with a significant $2.7 \%$ annual increase for females and $3.4 \%$ for males from 2001 to 2010 (Figure 14.2).

## Projections

The base of projection for the HD model for both sexes was 2001-2010. HD model 1 gave the best fit for both females and males. For both females and males the HD estimates were well above those due to demographic change alone and for males also much higher than the Nordpred projections (Figure 14.3, Table 14.1). The model projects that female case numbers will increase by $162 \%-235 \%$ between 2010 and 2040 and male cases by $157 \%-356 \%$, with proportionate increases in treatment rates (Table 14.2).

## 15. Female breast cancer

## Trends

Figure 15.1. Female breast cancer; case numbers, 1994-2010

Figure 15.2. Female breast cancer; age-standardised incidence rate, 1994-2010

There was a significant upward trend in breast cancer numbers for females between 1994 and 2010 of $4.0 \%$ annually. Some deviation from this trend can be seen at the time of commencement of BreastCheck in 2001, and at the time of its extension to the south and west of the country in 2007 (Figure 15.1) but this seems to be overlaid on a steady long-term upward trend. A similar pattern, but with a smaller rate of increase ( $1.8 \%$ annually) can be seen for age-standardised incidence rates (Figure 15.2).

## Projections

The base of projection for the HD model was 1994-2010. Two HD models-1 and 4-gave an equally good fit, but give quite different estimates, so both are presented here (Figure 15.3, Table 15.1). HD model 1 projects an increase of $152 \%$ in cases between 2010 and 2040, while HD model 4 projects an increase of 55\%. The Nordpred projection (an increase of $113 \%$ ) lies between the two HD projections, with proportionate increases in treatment rates (Table 15.2).

## 16. Cancer of the cervix uteri

## Trends

Figure 16.1. Cancer of the cervix uteri; case numbers, 1994-2010

Figure 16.2 Cancer of the cervix uteri; age-standardised incidence rate, 1994-2010

There was a significant upward trend in cases of cancer of the cervix uteri, of $4.5 \%$ annually between 1994 and 2010. Although there is some year-to-year variation, this trend seems steady, with no apparent impact of the introduction of the populationbased screening programme, CervicalCheck, in 2008 (Figure 16.1). There was a similar pattern for age-standardised incidence rates, with an increase of $1.9 \%$ annually (Figure 16.2) although a model with no significant trend before 2006 and an annual percentage increase of $3.5 \%$ ( $95 \%$ confidence limits $1.4,5.7$ ) from 2006 to 2010 fitted the data equally well as the linear trend shown here ( $p=0.05$ ). The more conservative long-term trend was chosen, as the recent increase is likely to be partly due to the initiation of national cervical screening.

## Projections

The base of projection for the HD model was 1994-2010. HD model 1 gave the best fit. The HD estimates were well above those due to demographic change alone (Figure 16.3, Table 16.1). The Nordpred projections were close to those of the HD model and both project that case numbers will increase by $77 \%-88 \%$ between 2015 and 2040, with proportionate increases in treatment rates (Table 16.2).

## 17. Cancer of the corpus uteri

## Trends

Figure 17.1. Cancer of the corpus uteri; case numbers, 1994-2010

Figure 17.2. Cancer of the corpus uteri; age-standardised incidence rate, 1994-2010

Estimated annual percentage change ( $95 \%$ confidence limits)

$$
1994-2010 \quad 2.3 \quad(1.6,3.1)
$$

There was a significant upward trend in cases of cancer of the corpus uteri of $4.5 \%$ annually between 1994 and 2010 (Figure 17.1). There was a similar trend, a $2.3 \%$ annual increase, for age-standardised incidence rates (Figure 17.2).

## Projections

The base of projection for the HD model was 1994-2010. HD model 4 gave the best fit. The projected number of cases from this model was a little below that due to demographic change alone (Figure 17.3, Table 17.1) and also below the Nordpred projections. The models project that case numbers will increase by $62 \%-90 \%$ between 2015 and 2040, with proportionate increases in treatment rates (Table 17.2).

## 18. Cancer of the ovary

## Trends

Figure 18.1. Cancer of the ovary; case numbers, 1994-2010

Figure 18.2. Cancer of the ovary; age-standardised incidence rate, 1994-2010

Estimated annual percentage change (95\% confidence limits)

```
1994-2010 -0.6 (-1.4, 0.2)
```

There was a significant upward trend in cases of cancer of the ovary of $1.4 \%$ annually, between 1994 and 2010 (Figure 18.1). The trend in age-standardised incidence rates was downwards ( $0.6 \%$ annually) but not statistically significant (Figure 18.2).

## Projections

The base of projection for the HD model was 1994-2010. HD model 3 gave the best fit. The projected number of cases from this model was less than that due to demographic change alone but close to the Nordpred projections (Figure 18.3, Table 18.1). The models project that female case numbers will increase by $34 \%-44 \%$ between 2010 and 2040, with proportionate increases in treatment rates (Table 18.2).

## 19. Cancer of the prostate

## Trends

Figure 19.1. Cancer of the prostate; case numbers, 1994-2010

Figure 19.2 Cancer of the prostate; age-standardised incidence rate, 1994-2010

There was a significant upward trend in cases of cancer of the prostate of 9.1\% annually between 1994 and 2004 and of 4.4\% annually between 2004 and 2010 (Figure 19.1). The trend in age-standardised incidence rates was similar but smaller: 7.6\% annually between 1994 and 2004 and 1.3\% from 2004 onwards (Figure 19.2).

## Projections

The base of projection for the HD models was 2004-2010. HD model 4 gave the best fit. The projected number of cases from this model was similar to that due to demographic change alone but much less than the Nordpred projection (Figure 19.3, Table 19.1). The models project that case numbers will increase by $104 \%-288 \%$ between 2010 and 2040, with proportionate increases in treatment rates (Table 19.2).

## 20. Cancer of the kidney and renal pelvis

## Trends

Figure 20.1. Cancer of the kidney and renal pelvis; case numbers, 1994-2010

Figure 20.2. Cancer of the kidney and renal pelvis; age-standardised incidence rates 1994-2010
females
 1994-2010 $3.4 \quad(2.6,4.2) \quad 1994-2010 \quad 2.9 \quad(2.2,3.7)$

There was a significant 5.3\% annual upward trend in cases of cancer of the kidney and renal pelvis for females between 1994 and 2010 and $5.4 \%$ for males (Figure 20.1). Trends in age-standardised incidence rates were smaller but also statistically significant: a $3.4 \%$ annual increase for females and $2.9 \%$ for males (Figure 20.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for both males and females. For both females and males the HD estimates were well above those due to demographic change alone and a little above the Nordpred projections (Figure 20.3, Table 20.1). For males the Nordpred projections were below the $95 \%$ confidence limits of the HD model. The models project that female case numbers will increase by $58 \%-153 \%$ between 2015 and 2040, and male cases by 24\%-124\%, with proportionate increases in treatment rates (Table 20.2).

## 21. Cancer of the bladder

## Trends

Figure 21.1. Cancer of the bladder; case numbers, 1994-2010
females

Estimated annual percentage change (95\% confidence limits)
$-0.2 \quad(-1.5,1.1)$
males

Estimated annual percentage change (95\% confidence limits)
1994-2010 -0.6 (-1.0, -0.1)

Figure 21.2. Cancer of the bladder; age-standardised incidence rates 1994-2010
females males

There was no significant trend in case numbers for cancer of the bladder for either females or males (Figure 21.1). Trends in agestandardised incidence rates were significantly downwards for both sexes: $2.1 \%$ annually for females and $2.6 \%$ for males (Figure 21.2).

## Projections

The base of projection for the HD models for both sexes was 1994-2010. HD model 3 gave the best fit for both males and females. For both females and males the HD estimates were well below those due to demographic change alone (Figure 21.3, Table 21.1). Nordpred and HD models gave similar figures for females, but the Nordpred projections were much lower than the HD projections for males. There is an apparent discontinuity between the actual 1994-2010 incidence and the HD projections for males. The models project that female case numbers will increase by $45 \%-65 \%$ between 2010 and 2040 and male cases by 9\%$33 \%$, with proportionate increases in treatment rates (Table 21.2).

## 22. Cancer of the brain and other central nervous system

## Trends

Figure 22.1. Cancer of the brain and other central nervous system; case numbers, 1994-2010

Figure 22.2. Cancer of the brain and other central nervous system; age-standardised incidence rates 1994-2010

There was a significant increase in case numbers of cancer of the brain and central nervous system for both sexes: $2.4 \%$ annually for females and 2.0\% for males (Figure 22.1). There was no significant trend in age-standardised incidence rates (Figure 22.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for females and model 1 for males. For both females and males the HD estimates were similar to those due to demographic change alone and for males the Nordpred projections were much lower than the HD projections (Figure 22.3, Table 22.1). The models project that female case numbers will increase by 41\%-62\% between 2010 and 2040 and males by $30 \%-149 \%$, with proportionate increases in treatment rates (Table 22.2).

## 23. Hodgkin's lymphoma

## Trends

Figure 23.1. Hodgkin's lymphoma; case numbers, 1994-2010

Figure 23.2. Hodgkin's lymphoma; age-standardised incidence rates 1994-2010

There was a significant upward trend in case numbers of Hodgkin's lymphoma for both sexes: $3.3 \%$ annually for females and $3.5 \%$ for males (Figure 23.1). Trends in age-standardised incidence rates followed the same pattern, with a significant $1.6 \%$ annual upward trend for females and 1.7\% for males (Figure 23.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for both males and females. For both females and males the projected number of cases from this model was a little above that due to demographic change alone, and higher than the Nordpred projections for females (Figure 23.3, Table 23.1). The model projects that female case numbers will increase by $11 \%-30 \%$ and male cases by $41 \%-44 \%$, with proportionate increases in treatment rates (Table 23.2).

## 24. Non-Hodgkin's lymphoma

## Trends

Figure 24.1. Non-Hodgkin's lymphoma; case numbers, 1994-2010

Figure 24.2. Non-Hodgkin's lymphoma; age-standardised incidence rates 1994-2010

The trends for non-Hodgkin's lymphoma were similar to those for Hodgkin's lymphoma. For females there was a significant upward trend in case numbers of $3.7 \%$ annually, and for males, $3.9 \%$ annually (Figure 24.1). Age-standardised incidence rates increased by $1.6 \%$ annually for females and by $1.7 \%$ for males (Figure 24.2).

## Projections

The base of projection for the HD model for both sexes was 1994-2010. HD model 4 gave the best fit for both sexes. For both females and males the HD estimates were similar to those due to demographic change alone (Figure 24.3, Table 24.1). The Nordpred projections for females were above those from the HD model, while the male Nordpred projections were a little lower. The models project that female case numbers will increase by $68 \%-98 \%$ and male cases by $62 \%-83 \%$, with proportionate increases in treatment rates (Table 24.2).

## 25. Leukaemia

## Trends

Figure 25.1. Leukaemia; case numbers, 1994-2010

Figure 25.2. Leukaemia; age-standardised incidence rates 1994-2010
females males

Estimated annual percentage change ( $95 \%$ confidence limits)
1994-2010
$0.1 \quad(-0.9,1.2)$

Estimated annual percentage change (95\% confidence limits)

| $1994-2004$ | 3.1 | $(1.8,4.3)$ |
| :--- | ---: | :--- |
| $2004-2010$ | -4.1 | $(-6.6,-1.6)$ |

There was a significant upward trend in leukaemia case numbers for females of $1.7 \%$ annually. For males there was a significant upward trend of $4.6 \%$ annually between 1994 and 2004, with no significant change in case numbers from 2004 onwards (Figure 25.1). There was no significant change in female age-standardised incidence rates between 1994 and 2010, while for males there was a $3.1 \%$ annual increase between 1994 and 2004, and a $4.1 \%$ annual fall after 2004 (Figure 25.2).

## Projections

The base of projection for the HD models for females was 1994-2010 and for males 2004-2010. HD model 3 gave the best fit for both sexes. For females there was reasonable agreement between the HD and Nordpred model, but for males the projected numbers were quite different (Figure 25.3, Table 25.1). The HD model projects a fall in cases, while Nordpred projects an increase; both were below the increase based on demographic change. The models project that female case numbers will increase by $31 \%-92 \%$ between 2015 and 2040, while male cases are projected to increase by $39 \%$ (Nordpred) or decrease by $57 \%(H D)$, with proportionate changes in treatment rates (Table 25.2).

## 26. Discussion

### 26.1 Summary

This report shows, as have previous projections of cancer numbers by the Registry [17, 18], that the number of new cancers in Ireland is expected to increase significantly in the next three decades. Based only on changes in demography, the total number of new invasive cancers will almost double between 2010 and 2040, from 28,480 to 55,991 . In the decade 2010-2020 alone, we expect a $25 \%$ increase in new cancer cases, with a proportionate increase in the numbers of treatments.

With the exception of leukaemia in males, the number of cancers is projected to increase for all sites between 2010 and 2040 (Figure 26.1).

Figure 26.1. Projected percentage increase in number of cancer cases 2010-2040, by cancer site and sex females
males

The most rapidly increasing cancers in coming decades are likely to be those of skin-both melanoma and non-melanoma-in both sexes. Cancers of the upper gastrointestinal tract—oesophagus, pancreas and hepatobiliary tract—are also expected to increase by over 100\% by 2040.

Of the other common cancers

- cancers of the colon and rectum are projected to increase largely in line with demographic change, by 120\%-130\% between 2010 and 2040;
- lung cancer incidence is rising more rapidly in females than in males and by 2040 the rate is projected to increase by $136 \%$ in females (Nordpred) and $52 \%$ in males;
- female breast cancer is difficult to project, due to recent short-term variations in incidence trends, but is expected to increase by about $130 \%$ between 2010 and 2040 . However one HD model projects a much slower rate of increase for females;
- future trends in prostate cancer rates are unclear; the HD models project an increase of $104 \%$ in new cases by 2040, while Nordpred projects an increase of $288 \%$; the latter, which is based on the rapid increase in rate in the early 2000s, driven by PSA testing, seems implausible;
- the models for cancer of the bladder and for leukaemia in males were heterogeneous, and future trends in these are difficult to project.

### 26.2 Comparison with previous projections

Table 26.1 compares the projections in this report to those made in 2008 [18]. For all invasive cancers combined, the projections of all models in this report were lower than those made in 2008. This was largely due to the revision of CSO population projections following the 2011 census. The difference in projected case numbers was larger for males than for females, probably due to the rapid increase in prostate cancer in the late 1990s and early 2000s, which had not levelled off when the previous projections were made. As the definition of "head and neck" cancers differed between the two reports, the figures are not comparable. Projections for oesophageal and stomach cancers for females, and for stomach cancer in males, are higher than in the previous reports, but lower for oesophageal cancer in males. Projections for colorectal cancer are slightly lower than in the previous report. Melanoma and non-melanoma skin cancer projections were variable, some higher and some lower than the previous figures. Projections for cancer of the kidney and renal pelvis in females were well below those in the previous report; the expected increase in renal cancer incidence, probably due to incidental findings on imaging [25-27], was not sustained. Projections for cancers of the bladder, brain and CNS and for lymphoma were all a little lower than previous projections. Projections for prostate cancer or leukaemia in males are not in Table 26.1 as projections for these were not made in 2008.

## Notes:

1. NMSC: non-melanoma skin cancer
2. Head and neck includes larynx in this report but not in 2008.
3. Total of projections for colon and rectum.
4. Total of cervix, corpus uteri and ovary from this report; included some rare additional sites in 2008.
5. CNS: central nervous system
6. Total of projections for Hodgkin's and non-Hodgkin's lymphoma in this report
7. HD model 1
8. HD model 4

### 26.3 Strengths and limitations

The strengths of the approach used here are that the methods are robust and widely used, use all the available data and make a minimal number of assumptions about the underlying trends. We also, for the first time, provide estimates of future demand for cancer treatments, with the caveat that these depend on the stability of treatment patterns into the future.

The most significant limitation of the approach is that it assumes that current incidence trends will continue unchanged into the future. The use of projection models can be useful in assessing future needs for cancer services and, in some situations, for estimating the impact of measures to reduce cancer incidence. However, models simplify what is a complex combination of changing risk factors, diagnosis, screening and classification. Although historic trends can be fitted using more complex models than those shown here [28] these models also make more assumptions about the continuity of trends into the future. Even over the relatively short period covered by the National Cancer Registry, incidence trends for a quite a few cancers have changed significantly and therefore the assumption of continuity of trends into the future is not very firmly based. The methods used here are similar to those in previous projections [18] and may be partially validated by comparing previous projections with current data (Figures 26.2, 26.3). In general, the previous projections for 2010 are close to the actual 2010 incidence figures for most sites, although the projections slightly underestimated the increase in cancer numbers for the majority of sites. For males there was a slight underestimation of numbers of cancers of lung, stomach and melanoma and, for females, an under-estimation of numbers of non-melanoma skin cancers and an over-estimation of brain and CNS cancer. However this comparison is for only a few years following the publication of the previous projections and the validity of longer-term projections is less secure.

Another limitation of modelling is the sometimes large discrepancies between the results of different modelling approaches to the same data. Different models may project quite different trends, as can be seen in this report for cancers of the lung, female breast, bladder, and for leukaemia in males. For most cancers, case numbers by age group and year are relatively sparse and subject to considerable year-to-year variation. Models based on age-specific rates may place too much reliance on apparent trends in these rates; on the other hand ignoring these would be mistaken if there are real differences in trend between different age groups. Even when rates are modelled for all age groups combined, an increase in case numbers may fit an exponential growth curve closely, although long-term exponential growth in cancer rate is extremely unlikely. Consequently, less reliance can be placed on projections for 20 years than on those for 10 . It must also be remembered that for some cancers, the period which was the basis of projection was less than 10 years. The Nordpred model has the advantage of using a fixed power relationship for all cancers, and avoiding the exponential trends sometimes fitted by the HD models.

1. Projected case numbers are taken from "Cancer projections 2005-2035", National Cancer Registry, 2008 [18].

For a number of cancers, there were substantial differences between the HD and Nordpred projections. There were a number of possible reasons for these discrepancies.

1. Nordpred software needs a minimum of three 5 -year periods and always used the entire period 19962010 as the base of projection, even when there were changes in trend during that period. HD projections used a shorter base of projection when there were recent significant changes in incidence rate. Nordpred is therefore more reliable when trends were stable over the entire period.
2. The HD models which fit best in most cases (models 3 and 4) did not fit trends separately to each age group, whereas Nordpred does, so in cases where the trends for younger patients were different from those for older patients, the models differed. This may be seen as a weakness of the HD model, but the number of cases in each age group is small and the modelled trends by age group are not necessarily reliable.
3. For a small number of sites, the HD log-linear age-period model gave the best fit, although exponential growth in cancer numbers is implausible over long periods. In those cases, the Nordpred estimates are probably more reliable, especially in the longer term.

As a consequence, although statistical tests for choosing the best fit of a model to the historic data are a reasonable guide, there is some degree of subjectivity in the final choice of model. For this reason we have offered a number of possible models in this report, where the best choice was not obvious. A review of different methods for case projections has suggested that Nordpred projections may be more reliable in the longer term [22,29], but this has not yet been verified against real data.

As population projections are now available up to 2040 we have attempted to make some projections of cancer case numbers for the same period. However, these need to be viewed with caution, as there have been significant changes in incidence trends for many cancers in the past two decades, as well as documented changes in risk factor prevalence. Projections for the next decade (2015-2025) are likely to be reliable; our comparison of previous projections to actual incidence supports this. For longer periods, the best we can hope for is that projections can give some general indication of future cancer burden. As few cancers currently have a decreasing trend in incidence rate, demographic projections tend to be the most conservative and provide a "best-case" scenario for most cancers.

### 26.4 Determinants of changing cancer incidence

Trends in cancer incidence are determined principally by two elements: population change and changes in exposure to risk factors. More information is usually available on population trends, which are readily incorporated into projections of cancer numbers. A number of projections have been attempted on the basis of current and projected changes in risk factor prevalence [30-34] but there is a long lag period, estimated at 15-20 years for solid tumours, between changes in risk factor prevalence and the development of the associated cancers, so these models are difficult to verify. Most projections are based on the assumption that risk factor prevalence tends to be stable over long periods of time, changes only slowly and can be modelled indirectly from changes in age-standardised rate. While this may be valid for some risk factors, others, such as obesity, are increasing rapidly. Case numbers may also be affected by a number of other factors: screening programmes, changes in medical practice leading to the discovery of more incidental cancers, advances in diagnostic procedures or changes in histological classification and changes in the completeness of registration. These may lead to short-term changes in incidence which are difficult to incorporate into models and the assumption is generally made that, apart from screening programmes, their impact is slight.

## Demographic change

The models of population change provided by the CSO make a number of assumptions with regard to mortality, migration and fertility. Only the first of these is likely to have any major impact on future cancer numbers, as the others affect the younger population, which has a low cancer incidence. The projections used here project a continuing improvement in life expectancy of approximately one year of life for each five calendar years between 2010 and 2046. However the increase in life expectancy at birth has been more rapid than this since the late 1990s, and it is possible that the number of older people in the population will increase more rapidly than is projected in the CSO figures. This would result in a larger number of cancer cases than projected here.

## Risk factor prevalence

Four risk factors have been shown to determine the majority of the attributable risk of cancer (excluding nonmelanoma skin cancer) in the UK [35]-tobacco [36], diet (including energy balance, obesity and physical activity) [37], alcohol [38] and reproductive factors [39, 40]. No equivalent calculations have been done for Ireland, but given the similarity in lifestyle between the populations of Ireland and the UK, it is reasonable to assume that the distribution and prevalence of attributable risks due to these major factors are similar. In addition to these general risk factors, we must also consider some cancer-specific causes-UV light for skin cancers, H pylori for stomach cancer and HPV for cervical cancer.

## Tobacco

Although reliable long-term data on smoking prevalence are difficult to obtain for Ireland, it is estimated that smoking prevalence in males was $35 \%$ in 1986-1987, falling to $32 \%$ by 1998, while, for females, prevalence remained at $31 \%$ throughout the 1990s [41, 42]. The SLÁN surveys [43] reported a smoking prevalence of $34 \%$ in males in $1998,27 \%$ in 2002 and $31 \%$ in 2007 and $32 \%, 27 \%$ and $27 \%$ in females in the same period. Data from the Office of Tobacco Control (OTC) shows a prevalence of $30 \%$ for males and $28 \%$ for females in 2002, falling to $25 \%$ in males and $22 \%$ in females in 2010 [44, 45] (Figure 26.4). Overall, there has been a fall of about $9 \%$ in smoking prevalence for males and of about $8 \%$ for females since 1986. The rate of decrease seems more rapid since about 2003. The HSE/OTC data show a rapid decline in smoking prevalence in younger adults, which is likely to be sustained.

## Diet and energy balance

Obesity and lack of physical exercise are probably more important in cancer aetiology than individual dietary components [46-48]. The most comprehensive data on diet, exercise and energy balance in Ireland come from the SLÁN surveys [45]. These show a steady increase in BMI and weight from 1998 to 2007. The percentage whose self-reported weight was in the "over-weight" or "obese" range increased from $51 \%$ to $59 \%$ (males) and $35 \%$ to $41 \%$ (females) in the same period. The largest increases in weight and BMI were in the oldest age group. Most age groups, apart from the oldest, reported a fall in their mean energy intake over this period, with falls in fat and carbohydrate intake. The percentage reporting that they had taken no exercise in the previous week also fell between 1998 and 2007. These reports are somewhat inconsistent with the BMI data, but point to the possible adoption of a healthier lifestyle.

Figure 26.4 Cigarette smoking in Ireland 1998-2010

## Alcohol

Alcohol consumption per adult seems to have peaked in 2000-2002 at over 14 litres alcohol/adult/year and has fallen slightly since then (Figure 26.5) [14]. Patterns of drinking may also have changed [14]. The number of heavy drinkers has fallen considerably in the younger age groups but much less in those 45 and over (Figure 26.6) [49].

Figure 26.5. Alcohol consumption(litres of alcohol per person), selected countries and OECD average 1990-2011

Figure 26.6. Percentage of drinkers who consumed alcohol above the recommended weekly limit in the previous 12 months 1998, 2020 and 2007

## Reproductive life

Parity, age at first birth, age at menarche and age at menopause are among the most important risk factors for breast cancer, as they are markers of oestrogen exposure. There is little information on the last two in Ireland. Mean age at menarche appears to have decreased from 13.5 in 1986 to 12.5 in 2007 [50]; no information could be retrieved on trends in age at menopause. Parity has fallen from 3.4, for females in the 1940 birth cohort, to 1.7 for those in the 1969 cohort (data from 2006) [51]. In the 2011 census, females aged 70+ reported 4.4 live births over their reproductive life, compared to 2.9 for those aged 50-54 [52]. Age of the mother at first birth has risen from 24.5 in 1950-1960 to 28.6 in 2002-2011 [53]. All of these trends suggest increasing lifetime oestrogen exposure.

### 26.5 Trends by cancer site

## All invasive cancer sites combined

Of the four most important modifiable cancer risk factors-tobacco consumption, alcohol abuse, obesity and changes in reproductive and hormonal patterns-the first two are decreasing in prevalence in Ireland, while the others are increasing. The overall impact of these changes on cancer trends is difficult to predict, but early reductions in incidence rates seem unlikely. The number of cases of invasive cancer is projected to increase from 28,480 in 2010 to almost 60,000 in 2040, based on demographic change alone, in the absence of any change in incidence rates. Similar trends can be seen if non-melanoma cancers of the skin are excluded. A worrying trend is the greater rate of increase in tobacco-related cancers in females.

It is estimated that the interval between initiation of a solid tumour and its diagnosis is 15 to 20 years, so most of the projected increase between now and 2030 has been determined by prior exposures and will not be affected by future preventive measures. Changes in lifestyle in the past decade are unlikely to have yet manifested in incidence changes, but the changes in tobacco and alcohol consumption should manifest as some reduction in cancer incidence rates in the next few decades.

## Tobacco-related cancers

Tobacco smoking has been implicated as a causal factor in many cancers [54]. However, the estimated relative risk due to smoking ranges widely, from 14.6 for laryngeal cancer in males to 1.2 for colorectal (Table 26.2).

Table 26.2. Estimated relative risks (RR) for current smokers aged 35 compared with never-smokers [36]

| cancer | males | females |
| :--- | :---: | :---: |
| larynx | 14.6 | 13.0 |
| lung | 21.3 | 12.5 |
| oesophagus | 6.8 | 7.8 |
| oral cavity and pharynx | 10.9 | 5.1 |
| urinary bladder | 3.0 | 2.4 |
| pancreas | 2.2 | 2.2 |
| ovary (mucinous) | - | 2.1 |
| stomach | 2.2 | 1.5 |
| liver | 2.3 | 1.5 |
| cervix | - | 1.5 |
| kidney and renal pelvis | 2.5 | 1.5 |
| colon-rectum | 1.2 | 1.3 |
| acute myeloid leukaemia | 1.9 | 1.2 |

The estimated increase in tobacco-related cancers in Ireland between 2010 and 2040 is, in general, greater for females than for males (Table 26.3). Cancer of the lung is projected to increase by $95 \%-196 \%$ in females and by $72 \%-121 \%$ in males, cancer of the oesophagus by $84 \%-140 \%$ in females and $112 \%-160 \%$ in males and cancer of the bladder by $45 \%-65 \%$ in females and $9 \%-33 \%$ in males. The projections for cancer of the head and neck are inconsistent-the HD model projects a larger relative increase in incidence in males, while Nordpred projects a larger increase in females. The overall projected increase between 2010 and 2040 in the number of tobaccorelated cancers listed in Table 26.2 is $110 \%-115 \%$ for females, and $83 \%-91 \%$ for males; these cancer sites represent approximately half of all invasive cancers, excluding non-melanoma skin.

| Table 26.3 Projected \% increase 2010-2040 in tobacco-related cancers: HD and Nordpred models |  |  |  |  |
| :--- | ---: | ---: | ---: | ---: |
| females |  |  | males |  |
|  | HD | Nordpred | HD | Nordpred |
| head and neck ${ }^{1}$ | $46 \%$ | $128 \%$ | $66 \%$ | $108 \%$ |
| oesophagus | $84 \%$ | $123 \%$ | $160 \%$ | $112 \%$ |
| stomach | $32 \%$ | $74 \%$ | $27 \%$ | $59 \%$ |
| colon | $116 \%$ | $117 \%$ | $156 \%$ | $104 \%$ |
| rectum | $83 \%$ | $110 \%$ | $105 \%$ | $77 \%$ |
| liver, biliary tract and gallbladder | $127 \%$ | $148 \%$ | $113 \%$ | $155 \%$ |
| pancreas | $140 \%$ | $172 \%$ | $152 \%$ | $129 \%$ |
| lung | $196 \%$ | $136 \%$ | $72 \%$ | $52 \%$ |
| cervix | $77 \%$ | $88 \%$ | - | - |
| ovary | $34 \%$ | $44 \%$ | - | - |
| kidney | $58 \%$ | $153 \%$ | $24 \%$ | $124 \%$ |
| bladder | $45 \%$ | $65 \%$ | $33 \%$ | $9 \%$ |
| all cancers listed above | $\mathbf{1 1 0 \%}$ | $\mathbf{1 1 5 \%}$ | $\mathbf{9 1 \%}$ | $\mathbf{8 3 \%}$ |

Note: The category "head and neck" corresponds largely to cancers of the oral cavity, pharynx and larynx in Table 26.2.

## Cancers of the head and neck

Cancers of the head and neck are a heterogeneous group, but tobacco and alcohol are important in their aetiology [55, 56]. HPV infection is considered a causal factor for cancers of the oropharynx [57], but has only a minor effect on overall head and neck cancer incidence [58]. The overall trend resembled that for other primarily tobacco-related cancers, with an increase in rate for females, but not males. This is reflected in the larger projected increase for females ( $48 \%-108 \%$ between 2010 and 2040) than for males, which was greater than projected from demographic change alone. The variability in trends for males has resulted in the Nordpred projection being higher than that of the HD model because, although there was no statistically significant trend in rates for males, the aggregate rate for males in 2006-2010 was higher than that for 19962000.

## Cancer of the oesophagus

The main risk factors for cancer of the oesophagus are smoking and obesity [59, 60]. Adenocarcinoma of the oesophagus is increasing in incidence, while squamous carcinoma is decreasing [23] and the interaction of these trends has led to a modest projected increase in incidence, slightly below the demographic trend for females and slightly above it for males.

## Cancer of the stomach

Helicobacter pylori is the most firmly established risk factor for this cancer in European populations [61, 62]. In common with most other European countries [63] cancer of the stomach in Ireland is decreasing in incidence. There are no reliable data on trends in prevalence of H pylori in Ireland, and the studies carried out have been on small and unrepresentative population samples. However, as the incidence of stomach cancer in Ireland remains $50 \%$ above that in most Nordic countries [63] it seems reasonable to expect that the incidence will continue to decrease as projected. The rate of this decrease is uncertain, as there appears to have been some levelling off of the downward trends in rate for both males and females, as evidenced by the differences between the Nordpred and HD projections.

## Cancer of the colon, rectum and anus

Dietary factors, including consumption of fruit, vegetable and fibre, are known to be protective against cancers of the colon and rectum, while obesity, red meat consumption and lack of physical activity are known to be causative factors [64-66]. Screening (which has not yet been introduced on a full population basis in Ireland)
may, in the longer term, also result in a reduction in incidence [67,68]. The incidence rate for these cancers has remained fairly constant since 1994, with a small increase in colon cancer in males. Consequently, the projected figures are very close to those expected from demographic change. Similar trends are seen in other European countries, although the Netherlands has had a recent increase in incidence [63].

## Cancer of the liver, biliary tract and gallbladder

As previously reported, there has been an increase in cholangiocarcinoma incidence in Ireland and other countries [24]. The reasons for this are unclear and some of the increase may be due to improved diagnostic localization. Alcohol abuse is the main aetiological factor for hepatocellular carcinoma, with chronic infective hepatitis being a secondary factor [57]. Viral infection, diabetes and cholelithiasis are possible risk factors for extrahepatic cholangiocarcinoma [69, 70]. All projections suggest a similar increase in rate over the next 25 years, of approximately 2 -fold.

## Cancer of the pancreas

Tobacco and heavy alcohol intake are important causative factors for cancer of the pancreas [54]. However, unlike some other tobacco-related cancers, female pancreatic cancer rates are not increasing, while there has been a small increase in male rates. However, only about $30 \%$ of pancreatic cancers are histologically verified and median survival is only 3 months of diagnosis, so diagnostic accuracy is not as high for this cancer as it is for others [71] and incidence rates are consequently less reliable. Because of the absence of any time trends in the historic data, projections based on the Nordpred, HD and demographic models were all similar.

## Cancer of the lung

Tobacco is the cause of the overwhelming majority of lung cancer, although radon is considered to contribute about $8 \%$ of the attributable risk [72]. There has been a long-term increase in female lung cancer incidence rates since 1994; however, there has been no increase between 2004 and 2009. Given the gradual decrease in female smoking rates in the 1990s, there is likely to be an eventual levelling-off in female incidence rates. For females, the consequence is that three quite different estimates of future case numbers fit the models reasonably well, with estimates of cases in 2040 ranging from 1693 (HD model 4) to 2830 (HD model 1). The Nordpred model, which assumes the greatest stability of trends over time, gives an estimate of 2260 female cases in 2040, and this intermediate estimate is the most plausible, although possibly an over-estimate if we are seeing the start of a levelling-off in rate. Male rates show a long-term decrease but, again, no real change between 2004 and 2010. For males the HD model gives a higher estimate than the Nordpred model, which lies outside the $95 \%$ confidence limits of the HD model.

## Melanoma of skin

The primary risk factor for melanoma is UV exposure (including sunbeds), with burning in childhood and adolescence probably more important than total sun exposure [73, 74]. The recent rate of increase in incidence rates for melanoma of skin is greater than for most other common cancers, and almost twice as fast for males as for females. The HD models, which are based on more recent trends, project much higher numbers than either the Nordpred or demographic models.

Non-melanoma cancer of skin
The primary risk factor for non-melanoma cancer of the skin is UV exposure (including sunbeds) [73, 74]. Incidence rates have been increasing since 2001 for both males and females at about 3\% annually. Evidence suggests that this is mainly due to recreational exposure [75]. For females the HD and Nordpred models give similar results, but for males the Nordpred estimates are much lower than those given by the HD model.

## Female breast cancer

The main risk factors for breast cancer are early age at menarche [76], late age at first birth [77] low parity [76, 77], late menopause [76] and breastfeeding [78]. Obesity [79] and alcohol consumption [80] also significantly increase the risk of female breast cancer. The Nordpred projections lie between the two HD projections for female breast cancer. Projections are difficult for this cancer because of the short-term effects of the introduction of a national breast screening programme, which was rolled out in two phases over a relatively long period between 2000 and 2009. Prior to the screening programme there was an upward trend in both numbers and incidence rate, which would be expected from the trends in earlier menarche and reproductive patterns previously described. It seems likely that this will continue, giving breast cancer numbers somewhat above the demographic model. The Nordpred projection, which is based on long-term trends, is the most plausible under these circumstances.

## Cancer of the cervix uteri

The main risk factors for cancer of the cervix are HPV infection, smoking, parity and oral contraceptive use [54, 57]. Changing sexual behaviour and an increase in HPV prevalence are probably the most important factors influencing recent trends in Ireland. However, the incidence is also affected by screening activity. Incidence tends to rise at the beginning of screening, and opportunistic screening may also increase incidence. However, a well-organised population-based programme would be expected to reduce incidence [81]. Although the national screening programme has only recently been introduced in Ireland, opportunistic screening has been occurring for some time at quite a high level. Both the HD and Nordpred projections are similar and suggest a doubling in case numbers between 2010 and 2040. However, the recent introduction of the national screening programme, CervicalCheck, should reduce these numbers.

## Cancer of the corpus uteri

Obesity is the best-attested risk factor for cancer of the corpus uteri [82]. The projected increase in numbers and rate is consistent with the reported increase in obesity in the population. The Nordpred projections are higher than those from the HD model and the demographic projections lie between the two.

## Cancer of ovary

A number of reproductive and hormonal risk factors have been identified for ovarian cancer. The risk of this cancer reduces with parity, breast-feeding, tubal ligation, hysterectomy and oral contraceptive use (for 5 years or more), but other aspects of the aetiology are still not well understood [83]. The trend in incidence rate has been downward since 1994 and the projected increase in numbers is small. Both the HD and Nordpred models suggest an increase of $34 \%-44 \%$, much less than the demographic projections.

## Cancer of prostate

Age, race, and a family history of prostate cancer are the only established risk factors for prostate cancer. Androgens, diet, physical activity, sexual factors, inflammation, and obesity have been implicated, but their roles remain unclear [84]. There was a rapid increase in prostate cancer cases in the 1990s and early 2000s, due to the widespread use of PSA testing [85], but this trend began to level off around 2004 and return to the rate of increase seen in the early 1990s. Due to the large variations in trend in the past two decades, the projections for this site vary widely and cannot be regarded as currently very reliable.

## Cancer of kidney and renal pelvis

Smoking and obesity are the main risk factors for cancer of the kidney [86, 87] although incidental discovery on abdominal imaging is also thought to contribute to rising incidence, especially in females [27, 88]. Cancer of the kidney and renal pelvis is increasing in incidence at a rate greater than that for all cancers combined, and there is consequently a high number of projected cases. For females, the HD and Nordpred projections gave
similar results, but for males the Nordpred projections were much lower than those from the HD method, and not much above the demographic projections. This may have been due to the relatively low incidence rates in 2006 and 2007, and the HD projections are probably more reliable.

## Cancer of bladder

Smoking accounts for about $50 \%$ of all bladder cancers [89]. Occupational exposures are also risk factors, while the role of diet and environmental pollution are unproven [90]. The incidence of cancer of the bladder is decreasing for both males and females. The Nordpred and HD projections were consistent for females, but different for males and much lower than those for demography only.

## Cancer of brain and other central nervous system

Cancers of the brain and other central nervous system are a heterogeneous group, with no common aetiological factors. There was no significant trend in incidence for either females or males. For females the demographic, Nordpred and HD projections were very similar. For males, the demographic projections lay between the HD and Nordpred projections. The Nordpred method projected almost no increase in male brain cancer numbers over the next 20 years.

## Hodgkin's lymphoma

The main aetiological agent for Hodgkin's lymphoma is Epstein-Barr virus, but the role of this common infection in the causation of the disease is unclear [91]. The number of incident Hodgkin's lymphomas is small and there are upward trends for both males and females. For females the HD projections were higher than either Nordpred or demographic projections, while for males the HD and Nordpred projections were similar.

## Non-Hodgkin's lymphoma

The aetiology of non-Hodgkin's lymphoma is poorly understood, with the only established risk factors being infection and immune dysregulation [92]. Epidemiological studies have suggested that certain environmental and occupational exposures and lifestyle factors may be associated with the risk of NHL; however, these factors are uncommon and can explain only a small portion of NHL cases. The upward trends in non-Hodgkin's lymphoma are almost identical to those for Hodgkin's lymphoma. The projections for HD, Nordpred and demographic models were all quite similar.

## Leukaemia

About 50\% of leukaemias are of lymphoid cell type and $25 \%$ are myeloid [93]. No important common aetiological factors have been identified for either cell type. Recent leukaemia trends in males are downwards, while there was no significant trend for females. Most of the decrease has been in lymphoid leukaemias and those described as "unspecified" [93]. Nordpred and demographic projections were similar for females, and higher than the HD projections. For males, the projections varied widely, with the demographic projections being highest, and the HD projections showing a 50\% fall in case numbers by 2040.

## 27. Conclusions

All the models described here project an increase of around one-third in cancer cases in the decade 20152025. For females the Nordpred estimate was of an increase of $41 \%$ while the HD and demographic projections were close to $30 \%$. For males the figures were a little higher, ranging from $33 \%$ (demography) to $47 \%$ (Nordpred). Almost all cancer types are expected to increase in number. This almost inevitable increase will place additional burdens on the cancer services, for diagnosis, treatment, support and aftercare.

We have assumed that current trends in incidence will continue into the near future. However, we have seen how, for three common cancers-breast, cervix and prostate-screening has led to a considerable increase in the number of diagnosed cancer cases; screening for colorectal cancer has recently begun and it is to be expected that novel methods of screening for other cancers will appear in the next decade. While some screening may eventually bring about a reduction in health service costs, screening will initially increase case numbers and costs above what might be expected from natural increase. The introduction of each new screening method must therefore be preceded by a careful cost-utility analysis.

With the ageing of the population, and improved life expectancy, the median age of cancer patients at diagnosis will increase. For all invasive cancers combined the percentage of patients aged over 70 is expected to increase, for females, from $31 \%$ in 2015 to $44 \%$ in 2025 and, for males, from $40 \%$ to $51 \%$. As a result there will not only be more cancer patients, but they will be older on average. This older population will have different needs, responses to treatment and susceptibility to side-effects. Clear guidelines on the assessment and treatment of older patients are urgently needed. Clinical trial data on older patients remains quite limited and there is a tendency to under-estimate the capacity of fit older patients to tolerate curative treatments. The combination of increasing incidence and improving survival of cancer patients will place a growing burden of follow-up on the cancer services. With greater life expectancy and better survival, the number of prevalent cases is increasing even faster than incident cases, with clear consequences for surveillance, support and aftercare services.

A further challenge is the growing availability and use of ever more sophisticated and expensive targeted therapy. The proportion of patients having chemotherapy in Ireland increased by 13\% between 2000-2004 and 2005-2009, and it is noticeable that most of this increase was in cancers where chemotherapy levels were previously quite low [94]. While the greater efficacy and more widespread use of chemotherapy has contributed to an improvement in survival [94, 95], the high cost of some therapies, particularly those for advanced disease, will need to be balanced against the benefits to the patient, and also against other priorities in cancer care. These decisions will become increasingly difficult as more therapies become available and life expectancy increases; they cannot be based on the length of survival alone, but also on the quality of this survival. The development of expensive therapies and screening interventions has driven a programme of research at the Registry into the economics of cancer care [96-99] both from the patient and the provider perspective. We have, for instance, investigated the cost-effectiveness of different methods of reducing morbidity and mortality from colorectal cancer [100]; is it best to set up a prevention programme, to establish a screening programme, or to provide more surgery, chemotherapy and radiotherapy?

Recognising the importance of outcome measures other than length of survival, the Registry has also developed an extensive programme of research to augment our data with measures such as patient- and carer-reported outcome measures, from physical and psychological well-being and patient experiences of cancer services, through employment issues, supportive care needs and financial problems [101, 102]. Drawing on our database of over 100,000 cancer survivors, we can examine these issues in large, representative population samples. This research continues to give us valuable insights into patient experiences and has allowed us to develop better methods of assessing the quality of service which patients receive. While patients
are generally happy with their quality of care, we have identified a number of remediable shortcomings, particularly in the areas of communication and information.

As noted throughout this report, projections of cancer cases based on existing trends in incidence are limited in their ability to predict the future cancer burden. More sophisticated methods, which can model trends in risk factors and attempt to predict the impact of measures such as programmes of prevention and screening, may be more useful, particularly in informing choices between different interventions such as prevention and screening. However, the overall conclusions from these projections are clear. Although we cannot modify the effects of demographic change, the majority of cancer risk is due to a small number of well-understood and potentially modifiable behaviours-UV exposure, smoking, alcohol consumption, diet and exercise. The majority of HPV infection is also now preventable, although other risk factors, such as hormonal and reproductive factors and Helicobacter pylori infection, are less amenable to change. Many of these risk factors are also implicated in the causation of cardiovascular and respiratory disease, and their reduction through programmes of prevention must be a high priority for health policy. Detailed and comprehensive information on risk factor prevalence and its distribution in the population is essential to target and monitor preventive programmes. Such information is patchy, episodic and lacking in detail in Ireland at present, a situation which needs to be addressed.

Obviously, reports such as this are dependent on accurate and comprehensive cancer registration. The National Cancer Registry has operated in Ireland since 1994 with the full cooperation of all health service providers and with the active assistance of histopathology laboratories, HIPE units and many others. In recent times, some hospitals have had to withdraw or reduce their level of assistance to us due to resource limitations, forcing us to partially suspend or restrict cancer registration in these hospitals. We hope that these restrictions will be temporary; we are working with some hospitals on ways of integrating our activities with other cancer data collection by the hospital, to reduce overlap and duplication. We look forward to continuing our productive partnership with all healthcare providers in Ireland, both public and private, in the future, and hope that the projections contained in this report will be of lasting value to them.
